## INTRODUCTION

The Civil Engineering Laboratory has developed propellant-embedded anchors as an alternative anchoring system. These anchors can be used in situations where conventional anchors are difficult to use or will not meet mooring design requirements. In the early stages, the anchors were developed for use by Navy salvage vessels in coral seafloors (NAVSHIPS 0994-002-6010; Smith, 1971). Since that time embedment anchors of varying designs and sizes have been tested and used in a variety of seafloors (Taylor, 1976; True and Taylor, 1976; True, 1977; Wadsworth and Taylor, 1976). Propellant-embedded anchors are being used because they are easy to precisely install with no chance of the anchor dragging out of position.

Of the anchors that have been installed for actual operational use, most have been in coral seafloors. These installations have usually been proof loaded to design capacity; however, few data on the ultimate holding capacities of the anchors have been acquired. Consequently, it is not known at what factor of safety these anchorages have been used. The factor of safety may have been small or quite large.

There has been no operational use of the propellant-embedded anchors in rock. An attempt to place a mooring for a semi-submersible drilling rig in rock using a coral type projectile was not successful. Several rock flukes for propellant-embedded anchors have been built and tested with sharply inconsistent results. If the performance of rock flukes could be made more consistent and predictable, it is likely they would be widely used because of their high efficiency and because mooring scopes could be reduced (Valent, 1973 and Wadsworth, 1976).

This report presents the results of a program of model and full-scale embedment anchor tests in coral and rock. The significance of the tests is discussed, and analyses of the test data are presented. Based on the test data, separate equations are developed for predicting holding capacity in coral and rock seafloors. This work was sponsored by the Naval Facilities Engineering Command and funded under the Ocean Facilities Engineering Program.

## CORAL ANCHORS

The configuration of the coral flukes has undergone many changes during the development of the various embedment anchors (Figures 1 through 6). The present coral fluke design is basically the same for each of the CEL anchors. The only difference is that the 20K and 10K coral flukes (Figures 5 and 6) have a spur on the bottom of the fluke. This spur was added to induce a keying action in soft coral seafloors. It also balances the mass of the projectile so the main fluke plate is close to the axis of the piston. The spur is not necessary on the larger 100K anchor.

### Previous Tests

Embedment anchors have been tested by both the Navy and the Army. Results of tests conducted in coral seafloors prior to this project are listed in Table 1. Most of these tests were of limited use in a data base because of the variation in fluke configurations and the lack of data on properties of the seafloor materials. Samples of coral from around the embedded flukes were collected by divers in two of the test series: the SUPSLAV anchor tests at Barbers Point, and the CEL 20K anchor installations for the Barking Sands Underwater Range Extension (BSURE) mooring. Diego Garcia and Argus Island are mooring and salvage reaction point installations in coral with the CEL salvage and 100K anchors, respectively. In these cases, no attempts were made to pull out the flukes, but proof-loads were applied, and these proof-load data mark a lower bound holding capacity. Review of the available data indicated additional coral tests were required to develop a method to predict holding capacities in coral seafloors.

### Barbers Point Tests

Barbers Point, Oahu was selected as the site for full-scale tests in coral. Testing at this site offered three advantages: (1) some knowledge of the seafloor properties already existed from the SUPSLAV tests, (2) a direct comparison to previously acquired data would be possible, and (3) support was available at nearby Pearl Harbor. In order to conduct as many tests as possible with the available resources, a lightweight propellant-embedded anchor (CEL 10K anchor, Figure 7) was chosen.

The Barbers Point tests were conducted in June 1978. Harbor Clearance Unit One provided the supporting personnel and equipment to install the anchors. The craft used was a LWT, an aluminum side-loadable warping tug. The anchors were raised and lowered using a bow A-frame and a 3-ton-rated pneumatic winch. After installation of each anchor, the winch was used to its capacity to proof load the embedded fluke.

All 12 anchors to be tested were installed in 1 day. The embedded flukes were then surveyed by an engineer-diver. Figure 8 is a photograph of a typical embedded fluke. Four of the flukes were embedded in coral beneath a sand layer and could not be inspected. Each site was photographed, fluke penetration and size of impact crater measured, site markers placed, and samples of loose coral collected from around the fluke.

The anchors were load tested by the USS BEAUFORT ATS-2. Loads were applied by connecting into the anchor downhaul with a wire rope led over a bow roller, taking out the slack with the capstan, placing the line in a carpenter stop, then applying load by backing down the ship. Loads were measured using an in-line load cell. Eight of the 12 anchors failed when the wire rope downhaul failed; only four flukes were extracted. Following the load tests the anchor sites were again inspected by divers. Figure 9 is a photograph of the same fluke shown in Figure 8 after loading. Note that there is no evidence of the fluke extracting or of the surrounding coral displacing; this was typical of the flukes that

could be inspected. Figure 10 is a before and after photograph of one of the flukes which did extract. Complete information on the results of the load tests is given in Table 2.

Review of the test results and procedures indicates that the recorded loads may have been considerably lower than the loads actually applied at the anchors. First, the load line to the anchors passed over the ship's bow roller. Friction and the inertia of this roller would result in different line tensions inboard and outboard of the roller. Second, the swell and sea under which the tests were conducted resulted in very rapid load applications (snap loads) that probably exceeded the load recorder's dynamic response capability. Third, one anchor that had been proof loaded to a nominal 26 kN from the installation craft was pulled out by the BEAUFORT at a measured load of only 4.5 kN. Fourth, eight of the 12 tests ended when either downhaul cables or mechanical connections at the fluke failed. All of these failures occurred at on-deck recorded loads much lower than the breaking strength of the failed mechanical parts (~260 kN).

#### BARSTUR Tests

The 20K coral embedment anchors that were installed off Nohili Point at the Barking Sands Tactical Underwater Range (BARSTUR) in August 1976 (see data in Table 1) provided an opportunity to conduct pull tests on previously installed anchors. The anchors had been used to moor a cable-laying ship during installation of the shore end of the cable runs coming in from the new, expanded range. Figure 11 is a sketch of the design of each mooring leg. Note that two 20K anchors were used for each mooring leg. Following this use, the buoys were removed from three of the five moorings, and the wire rope bridles and downhauls were laid on the bottom. The other two moorings were used to moor two large navigational buoys.

CEL requested and received permission from the Pacific Missile Test Center (PMTC) to perform pull tests on the six unused anchors. Since a detachment from Underwater Construction Team Two (UCT 2) was to perform a cable survey at BARSTUR in the summer of 1978, PMTC also granted CEL the use of the detachment to locate and buoy the anchors to be tested. A section of the bridle, the wire rope connecting two anchors at each mooring, was recovered and returned to CEL for testing. The downhauls and bridles had been submerged for 2 years with no corrosion protection, but the two sections tested broke at 329.3 kN and 258.1 kN. The rated breaking strength for this 7/8-inch-diameter 6x19 wire rope was 354.2 kN. The wire ropes, thus, seemed to be in satisfactory condition to place meaningful loads on the anchors (the original mooring design had assumed each anchor to hold 222.5 kN).

Load tests were performed with the USS BRUNSWICK (ATS-3) in the same manner as was used earlier at Barbers Point. A strap of nylon line was added to the load line to reduce the snap loads experienced at Barbers Point. Also, sea conditions were better, which allowed a more gradual loading. The anchors were surveyed before and after load testing, with the test results as shown in Table 3. In every case the wire rope downhaul failed, thereby establishing a lower bound holding capacity. Note that the failure loads are below the breaking loads of two test

sections of wire rope. It is thought the reasons for this are similar to those for a similar problem with the Barber's Point tests. Post-test diver surveys failed to show any displacement of the anchor or the surrounding coral.

#### Analysis of Test Data

The data from the Barbers Point 10K anchor tests, the BARSTUR 20K anchor tests, and the proof loading data for the 100K anchor from Diego Garcia and Argus Island were plotted as histograms with the normal curve added. Figures 12, 13, and 14 show these data. The 90% confidence limit, the holding capacity which will be exceeded 90% of the time, is plotted for each case. The confidence of exceeding the rated holding capacity is 95% for the 10K anchor, greater than 99% for the 20K anchor, and 88% for the 100K anchor.

The confidence limits and mean holding capacities given in the figures are conservative since only 3 of the 11 data points in the 10K test data and none of the 20K or 100K test data are actual anchor extractions. The data are either the maximum proof-load applied or the maximum recorded loads experienced before the wire rope downhaul failed. Actual anchor pullout loads would shift the curves in Figures 12, 13, and 14 further to the right than is shown. In addition, the wire rope failures at Barbers Point and BARSTUR were recorded at levels much less than the rated breaking strength. It is likely that much higher loads occurred but were not recorded on deck due to friction and inertia of the ATS bow sheave or a slow response from the load recorder.

#### Prediction of Holding Capacity

Data Base. An equation for predicting holding capacity in coral seafloors can be developed from test data only where the anchor flukes were pulled out. This places a restriction on the data base because it eliminates data from both proof-loading tests and tests that resulted in mechanical failure of anchor hardware. Table 4 lists all the data found on embedded anchor coral tests listed in Table 1. Where known, the values of parameters that are thought to have the most influence on holding capacity are listed in Table 4 for each test. The fluke mass ( $m$ ) and velocity ( $v$ ) provide a measure of the energy available for penetration. Fluke frontal area ( $F$ ) affects penetration while the fluke's embedded surface area ( $A$ ) determines the area over which the fluke and coral interact to provide holding capacity. Fluke load point eccentricity,  $e$ , and loading angle,  $\theta$ , define nonfrictional aspects of holding capacity. Load point eccentricity is defined as the ratio of eccentricity of the downhaul attachment point from the main fluke axis to the length of the fluke. Two coral properties, unconfined compressive strength ( $\sigma$ ) and the dry unit weight ( $\rho$ ), help to define the effect of the target material. Also included are the data from two model coral fluke tests performed at NWC, China Lake, in a chalky limestone that simulated a soft coral. Nineteen of these tests resulted in pullout of an anchor fluke and are listed separately in Table 5.

There are two major problems with this data base. First, an examination of Table 5 shows that in many cases parameters are unknown. Of particular concern is the absence of coral properties for the first 14

tests listed. Second, the load measurements for the three CEL 10K anchor tests at Barber's Point are not thought to be indicative of the loads applied to the flukes as previously discussed. These 17 tests cannot, therefore, be used to determine the relative significance of the various parameters affecting holding capacity. There are then only two tests, the model 20K tests at China Lake, that are usable for developing a predictive equation that is a function of fluke and coral parameters. However, this data base is too narrow to achieve a meaningful result.

Development of Empirical Holding Capacity Equation. In spite of the difficulties with the data, an effort was made to determine the relative significance of the parameters. This was done by performing linear regression analyses for different combinations of test parameters using a method described by Tolson (1970). No distinction was made between proof loads, pullout loads, or loads that caused hardware failures. The dominating parameters were found to be fluke mass and velocity. Some coral property, however, seems to be a necessary ingredient as it affects both penetration and pull resistance.

An equation was then developed for holding capacity,  $H$ , as a function of fluke mass,  $m$ , fluke velocity,  $v$ , and coral compressive strength,  $\sigma$ .

$$H = f(m, v, \sigma) \quad (1)$$

From dimensional analysis it can be shown that

$$H^3 = f(\sigma \cdot m^2 \cdot v^4) \quad (2)$$

or

$$H = k \cdot \sigma^{1/3} \frac{1}{2} m v^{2/3} \quad (3)$$

Equation 3 is dimensionally correct and shows that holding capacity should be strongly influenced by the kinetic energy ( $KE = 1/2 mv^2$ ) of the fluke and only moderately influenced by the coral's compressive strength (since  $H$  varies as the cube root of  $\sigma$ ).

It is not possible to test this equation against the data base because of the paucity of information on coral strength for the tests where anchors pulled out. However, because coral strength is not nearly as significant a parameter as kinetic energy, a plot was made of holding capacity versus just kinetic energy (Figure 15). Every test from Table 4, where the kinetic energy could be determined and the holding capacity was known (58 data points), is included except for the fifth CEL 10K anchor test at Barber's Point. This test was excluded because the load measurement was very inaccurate. The circled points in Figure 15 represent tests where pullout was achieved. The best fit equation for all the data is:

$$H = 0.068 KE^{0.58} \quad (4)$$

The best fit equation for the data points where pullout occurred is:

$$H = 0.024 KE^{0.684} \quad (5)$$

Both equations are made dimensionally correct by making the units of the constants the cube root of  $N/m^2$  when the kinetic energy is in joules. Single-sided lower bound 90% confidence limits are presented in Figure 15 along with each best fit line. What is very significant about both of these equations, and particularly Equation 5, is that the power of the kinetic energy term is very near the two-thirds power derived by dimensional analysis. This result also suggests that Equation 3 may be an appropriate equation for including coral properties. However, the determination of the empirical constant for Equation 3 requires additional data not presently available.

Equation 4 is more a summary of experience with various coral anchors than a predictor of holding capacity. This is because three-fourths of the data upon which it is based are proof loads and hardware failures. It provides a very conservative estimate of holding capacity. On the other hand, Equation 5 is based only on pullout data and does provide a true estimate of ultimate holding capacity. On Figure 15, lines have been marked at the kinetic energies of the four CEL propellant-embedded anchors at optimum ballistic performance with a coral fluke. Table 6 is a tabulation of the predicted mean holding capacities and the holding capacities expected to be exceeded 90% of the time for each of the anchors.

There are limitations to Equation 5. Because it does not take into consideration coral properties or fluke shape, its use is restricted to the fluke shape and range of properties given in Table 5. However, as shown by Equation 5 and as discussed by Taylor (1976) for sediments, the holding capacity of a given propellant-embedded anchor is largely a function of the energy transferred to the fluke. Therefore, Equation 5 should have considerable usefulness in predicting the holding capacity in coral of the CEL propellant-embedded anchors.

## ROCK ANCHORS

### Previous Tests

The amount of existing data on propellant-embedded anchors in rock is considerably less than the data available for coral. The fluke designs which have been used have had mixed success (Smith, 1971; Taylor and Beard, 1973; Taylor, 1976). The SUPSALV rock fluke (Figure 16) was simply a coral projectile modified by increasing the fin's taper and hardening the projectile tip. The CEL 20K rock fluke design (Figure 17) was based upon the SUPSALV anchor results, the scale model tests conducted in a simulated rock medium (True, 1975), and the rock penetration work conducted by Sandia Laboratories (Young, 1970).

After testing of these flukes recommendations were made by the investigators to conduct further research and development on a rock fluke for embedment anchors. Following preliminary assessments (Wadsworth, 1976; Beard and Wadsworth, 1976) it was decided that the best approach

to developing an understanding of embedment anchor holding capacity in rock was to perform as many large-scale model tests as possible in a variety of rock types.

#### NWC, China Lake Tests

The first series of tests was conducted to explore the effect of different projectile shapes and ballistic parameters upon holding capacity. The tests were conducted in exposed outcrops of granite and extrusive basalt at the Naval Weapons Station, China Lake, Calif. Tests were conducted on land to allow a greater number of tests to be conducted with available funds. The anchor projectiles were launched by the Magnavox Company's propellant-embedded anchor test stand which was developed for firing the 7-pound Magnavox propellant-embedded anchor flukes on land. The propellant energy is transferred to the flukes by a piston that mates to the fluke and is inserted into the gun barrel. Using this launcher, a 1:3.75 geometric scale could be used assuming the 20K anchor as the prototype. Impact velocity of these models was the same as that of the prototype.

Eight different fluke shapes were used in these experiments. They are designated as Dart, Serrated Dart, Star, Cone, Stake, Serrated Stake, Tapered Stake, and Coral and are depicted in Figure 18. The Dart was considered to be the control fluke as it was geometrically scaled down from the 20K anchor rock fluke then in use. The Serrated Dart and Star are variations of this shape. The three stake shapes represent a significant departure from the DART as does the CONE. Each of the STAKE projectiles was shortened to keep the L/D ratio below 8. The weight lost by removing the fins and shortening the body was made up by using a heavier piston. The Coral was a scaled down coral fluke.

These shapes were all tested in a weathered granite and, with the exception of the coral fluke, in basalt as well. Only the coral fluke was tested in a chalky limestone, and those results are given in the section on coral anchor holding capacity. All holding capacities were measured in direct uplift using a calibrated hydraulic jack.

The results of the NWC, China Lake tests are given in Table 7.

#### Analysis of NWC Test Data

Eighteen tests were conducted in a weathered granite, and 12 tests were conducted in a vesicular basalt. The properties of these materials are given in Table 8.

Comparison of the tests, which were redundant with respect to the fluke and rock, indicates considerable variation in holding capacity even when similar conditions are maintained (compare tests 1, 2, and 6, tests 3 and 9, tests 4, 7, and 18). The most apparent reason for this variation is the amount of radial fracturing in the target caused by the penetration. These fractures relieve the normal stress on the projectile and result in lower holding capacities. The tendency to form radial cracks was greater in the dart-type projectiles than it was in the star, cone, and stake-type projectiles. Cracking was also greater when flukes were embedded in smaller outcrops or closer to the edge of large outcrops.

In basalt, all of the projectiles were damaged and would only penetrate if they impacted in an existing crack or joint. Two modified flukes were built. One design was a dart fluke with a blunter nose and a heavier after body, the other design was a heat-treated cone with the original nose shape and a heavier after body. The modified darts impacted, spalling off large pieces of rock, but did not penetrate. The heat-treated cones penetrated in both cases (tests 29 and 30) about one-half of their length. Even with a 4140 steel alloy fluke hardened to Rockwell C 34-36 to achieve excellent toughness characteristics, the nose was slightly bent.

The conical fluke was selected as the shape to use for all further rock tests. The frontal area of this shape increases evenly during penetration which continually compresses the surrounding rock. Because of this, the conical fluke had the greatest amount of surface area covered with a comminuted rock coating. This coated surface is the area of the projectile in which rock is actually bonded to the fluke due to the heat generated while penetrating. While this may or may not actually establish a rock-to-fluke bond, it certainly increases the surface roughness of the projectile and thus the frictional resistance to pullout.

The even increase in frontal area also eliminates the development of local high stress areas which lead to cracking of the rock, as was caused by the fins of the dart-type projectiles.

The final advantages of the conical projectile are more practical. It can be more easily forged in larger sizes and is amenable to heat treatment. The dart and star-type flukes have too much variation in cross-sectional thicknesses to permit heat treatment to the hardnesses required.

#### White Sands Missile Range Tests

Additional scale-model tests were conducted in 1978 using only the conical shaped projectile to establish a data base for developing a holding capacity equation. The tests were conducted by Sandia Laboratories at the White Sands Missile Range (WSMR) in outcrops of granite, basalt, limestone, sandstone, and shale. The same scale rock projectile was used as in the NWC tests; however, a larger piston was used because the Sandia launcher had a larger bore than the launcher used at NWC (see Figure 19).

Five rock flukes were shot into each of the five types of rock using Sandia Laboratories' pneumatic launcher (Figure 20). The flukes were then extracted using a calibrated hydraulic jack (Figure 21). Tests were made in direct uplift with displacement measured and plotted versus applied load. Core samples were taken at each test site and tested to determine properties. The properties of the rock at each site are given in Table 9.

Twenty-two of the 25 shots were embedded. Two of the three which did not penetrate were machined from bars which were cracked during heat treatment and so partially split upon impact. The third unsuccessful fluke was simply "rolled up" when it impacted the limestone target. Six of the 22 flukes which were embedded sustained damage to the base or were embedded at an angle which prevented pullout tests. These six were not extracted until 6 months later. To achieve extraction of these flukes, an attachment was welded to the fluke's base and then they were jacked out vertical to the rock surface. There is some doubt as to the

meaningfulness of this data because the embedded flukes were exposed to wetting and drying and freezing and thawing over the six-month period of their embedment. Finally they were heated to 315°C during welding. These actions should reduce the holding capacity of the flukes. This, in turn, would make estimates obtained from equations developed from the data base conservative.

There is one other possible mechanism, creep, which could reduce the holding capacity over a period of time. The effect of this factor was not explored in these tests.

The results of the WSMR tests are given in Table 10. Figures 22, 23, 24, 25, and 26 show typical fluke embedments and the post-extraction appearance of flukes for granite, basalt, limestone, sandstone, and shale, respectively. Note the relative degrees of damage to the target rocks caused by the embedment. Radial cracking was absent in all cases except the limestone. The granite tended to spall and crater on the weathered surface layer. The basalt damage was limited to the area impacted by the fluke and the larger diameter piston. The limestone, the most difficult target to penetrate, showed minimal amounts of surface damage. Successful embedments in the rock occurred where the rock surface was closely jointed or the fluke impacted near a joint. The sandstone was badly damaged by impact; the rock was shattered into 12-inch to 3-inch-sized blocks. The shale, which was very brittle and thin-bedded, was extensively cratered and shattered into 3-inch to 1/2-inch fragments. It was impossible to prepare a suitable compression test specimen from the shale core sample.

#### Analysis of White Sands Missile Range Data

If the tests in which the fluke failed to embed and the tests in which no effective holding capacity was developed are termed "unsuccessful," we can say that 100% of the granite tests, 80% of the basalt tests, 60% of the limestone tests, and 40% of the sandstone tests were successful. "Success" in this case being an embedded fluke which provided some measurable holding capacity. Table 11 lists these successful tests and their measured holding capacities. It also gives the mean holding ( $H$ ) capacity and standard deviation ( $\sigma$ ) for each rock type and for the collective data.

It can be observed from Table 11 that the holding capacity one may reasonably expect by shooting the rock fluke into an unknown type of rock is highly variable. The mean of all the listed tests is 54.97 kN. The standard deviation is 49.2 kN. One could say with 83% certainty that the anchor holding capacity would exceed 5.77 kN. The accuracy can be improved if one knows the test was conducted in granite, basalt, limestone, sandstone, or shale.

The holding capacities even in a single rock type show fairly wide variations. Properties of the rock types were obtained from a single core sample taken in the rock outcrop, with the test shots being made in the same outcrop usually within 15 feet of the core. The granite target was an exception. Tests 1-1, 1-2, and 1-3 were performed in the same granite outcrop but 70 to 80 feet away from the part that was cored. Although the material properties of the various rocks are probably the same within such short distances from the core, the properties of the

rock mass must change enough to account for the variation in the test results. For example, the material properties of the rock at two sites could be identical, but if one test is conducted near a joint and the other in a fairly intact portion of the outcrop, the test results would be quite different.

In an actual emplacement of the CEL-type embedment anchors, the anchors are fired upon touchdown. No provision is made for precise positioning of the anchor before firing. Thus, a similar variation in possible holding capacities should be expected.

Another source of the variation of holding capacities within one rock type is the deformation to the fluke. The amount of damage to the fluke in each test is described in Table 10. It was impossible to assess the influence such deformation has on the fluke's holding capacities, so it was ignored as an individual factor.

#### Development of Empirical Holding Capacity Equation for Rock Seafloors

Simple regressions of each target property versus holding capacity were performed as a first attempt at predicting anchor holding capacities. A computer program was used which evaluates the statistics of eight different forms of equations the simple regression may assume. The program then selects which equation best fits the data based upon the standard error of estimate and correlation coefficient.

The best evidence of existing relations was found between holding capacity ( $H$ ) and Poisson's ratio ( $\mu$ ),  $H$  and Youngs modulus ( $E$ ), and  $H$  and the rock quality designation ( $R'$ ) in decreasing order of correlation. The correlation with unconfined compressive strength ( $\sigma$ ), unit weight ( $\rho$ ), and porosity ( $p$ ) were low. The simple regression procedure was also applied individually to the maximum embedded diameter of the fluke ( $D$ ), the embedded length ( $L$ ), and the embedded surface area ( $A_s$ ). All of these had a low correlation to the holding capacity. Table 12 presents the results of the simple regressions.

Use of any of the equations listed in Table 12 for  $\mu$ ,  $E$ , or  $R'$  results in a lower standard error of estimate than the standard deviation for all tests given in Table 11. This means that knowing any one of these properties and applying the appropriate regression equation allows one to make a more confident prediction of the anchor's holding capacity. These equations will also allow some interpolation since the properties of targets other than the rocks tested may be substituted into the equation.

Further improvement in the accuracy of predictions may be possible by combining various independent variables in one function. The prediction method should also have some factor or physical fluke dimension included to allow extrapolation to larger size rock flukes. Trial equations were developed using the multiple linear regression method of Tolson (1970). The earlier trials are based upon results of polynomial regressions conducted on the relationship of individual independent variables to holding capacity. The various powers used are based upon those results. The combinations of variables used were based upon results from earlier trials.

Table 13 contains the results of the trials. Note that some of the equations were developed from a set of 14 data points (White Sands tests) and some from 16 data points (White Sands tests plus two data

points from the NWC, China Lake tests). The NWC data and the WSMR shale data could not be used in some trials because of a lack of data on some of the variables. Trials developed from 16 data points which appeared significant were also developed using 14 data points to afford comparison with other trials.

Independent variables used to develop the trial equations are:

D = maximum embedded diameter of the fluke, cm  
L = maximum embedded length of the fluke, cm  
 $\sigma$  = unconfined compressive strength of target, MPa  
 $\rho$  = unit weight of target, g/cm<sup>3</sup>  
E = Young's modulus of target, GPa  
 $\mu$  = Poisson's ratio for target  
R = Rock Quality Designation for target  
p = porosity of target material, percent  
z = depth of crater in target following embedment, cm  
m = projectile mass, kg  
v = projectile velocity, m/s

Trials number 1 through 11 explored equations that used only the independent variables which were properties of the target rock. Most of these trial equations reduce the range of the 83% confidence interval given in Table 11 for all the data. They have two failings, however: (1) they do not contain any variables which account for the variability between holding capacity in the individual targets, and (2) they do not contain any variables which allow the projectile size to be varied.

Trials 12 through 30 use various powers of the maximum embedded diameter, D, and the embedded length, L, with the variables describing target properties. Trials 31 through 34 use the projectile mass, m, and impact velocity, v, as the projectile descriptive variables. D and L are effective in correcting the two failings mentioned above; m and v, however, are the same in almost all of the tests and so do not improve the predictions of the earlier trials.

Development of trial equations 35-40 followed a different path than the previous trials. A trial equation was developed from a theoretical viewpoint. It was assumed that the holding capacity is a function of the residual stress in the rock acting on the embedded surface area of the fluke. Dividing the modulus, E, of the target rock by the Poisson's ratio,  $\mu$ , for the rock will give the stress per unit lateral strain for elastic conditions. The amount of lateral strain induced would in turn be a function of the volume of rock displaced by the fluke.

Holding capacity, H = f (embedded surface area x residual stress)

If the fluke is idealized as a simple right circular cone,

$$H = k_1 \frac{\pi}{2} D \left( \frac{D^2}{4} + L^2 \right)^{1/2} \left[ E \mu^{-1} \left( \frac{\pi}{12} D^2 L \right) \right]$$
$$H = k'_1 E \mu^{-1} D^3 L \left( \frac{D^2}{4} + L^2 \right)^{1/2}$$

where  $k_1, k'_1$  = constants

$E$  = Young's modulus, GPa

$\mu$  = Poisson's ratio

$D$  = maximum embedded diameter, cm

$L$  = embedded length, cm

This equation can be expressed in a form amenable to the multiple regression methods outlined earlier by taking the log of both sides

$$\log H = k + \log E - \log \mu + 3 \log D + \log L + \frac{1}{2} \log \left( \frac{D^2}{4} + L^2 \right)$$

The preceding considers only elastic conditions. The embedment in natural rock targets is not strictly elastic. Targets which are jointed, fractured, or in which porosity is significant are less likely to develop residual stresses. This effect was included in the above equation by multiplying by the rock quality designation  $R'$  (trial 36). This is the percent length of a core sample which is composed of sections longer than four inches. Thus rock with a large number of joints will have a low RQD value. The RQD does not take into effect porosity,  $p$ , of the rock which also tends to prevent the development of residual stresses. So  $1-p$  was used to factor in this influence in trial 37.

One other parameter was tested in an attempt to combine the effects of porosity and fracturing. This is the depth of the crater,  $z$ , created by impact (trial 38). The volume of the crater would describe the rock condition better; however, the only measurements of the crater taken were depth.

Trials 41 and 42 were based upon the earlier findings of polynomial regressions performed on the relationship of embedded surface area to holding capacity. The best fit was a third order equation. Cubing the expression for volume and then adding the target properties which determine state of stress results in the combination of variables shown.

Equation 41 had the highest correlation of those tried. The standard error of estimate is quite high compared to others. The equation with the lowest standard error of estimate was number 8. The trend seemed to be that the simpler the equation, the lower the standard error of estimate. The more complex the equation, the higher the correlation coefficient. In fact, none of the trial equations had an error of estimate lower than that found in the simple regression between Poisson's ratio,  $\mu$ , and holding capacity.

Because the best simple regression was found between Poisson's ratio and holding capacity, the regression was repeated after normalizing the holding capacities by the kinetic energy of the flukes. This changes the coefficients in the equation, but not the statistical evaluation.

The trial equation with the best fit to the test data with respect to minimizing the standard error of estimate would be then

$$H = \frac{1}{2} mv^2 * \mu * 1.96 \times 10^{-3} \quad (43)$$

This equation makes allowance for use with larger size projectiles through the kinetic energy term. The trial equation with the lowest standard error of estimate which does include a variable relating to projectile size is Equation 15:

$$H = 43.01 - 195.18 D + 21.42 L - 1.00 \sigma + 142.36 \rho \quad (15)$$

Equation 41 results in the highest correlation coefficient followed closely by Equations 26 and 28.

$$H = -27,799.65 + 1.40 D^6 - 935.67 D^2 - 0.40 L^3 + 602.48 L \\ - 18.25 E + 1,631.57 \mu + 12,929.01 \left( \frac{R}{100} \right) \\ + 24,547.86(1-p) \quad (41)$$

A 20K embedment anchor rock fluke has been designed and is shown in Figure 27. This fluke will be tested in Fiscal Year 80. Equations 15, 41, and 43 were applied to see what holding capacities would be predicted for this larger fluke. Full embedment of the 20K rock fluke to the protective collar was assumed. Equations 15 and 41 extrapolated very poorly to this anchor size. Equation 43 gave results that seem in the right order of magnitude (1.78 MN to 0.250 MN (400 to 56 kips) as the rock was varied from granite to sandstone (Table 14)).

Equations 26, 32, and 34 were also tried. Equation 26 gave predictions that seem too high and that did not vary with rock type. Equation 34 gave predictions that seem too low (94.1 to 4.02 kN). Results from Equation 32 seem of the right magnitude, but as with Equation 26, the predictions varied little as rock type changed. This lack of variation seems to be a weakness with Equation 32 because the WSMR tests results seemed to be quite strongly influenced by rock properties.

The risks of extrapolating any of the equations beyond the as yet narrow data base are apparent. At present it seems that Equation 43 or a similar equation offers the best hope for developing a general equation to predict holding capacity in rock. The form of Equation 43, where the fluke's kinetic energy has been normalized into the holding capacity, needs to be tried with other rock parameters, combinations of rock parameters, and with the inclusion of different anchor sizes.

## SUMMARY

A review of available information on propellant-embedded anchor tests and installations in coral seafloors revealed that with few exceptions, insufficient data were gathered to allow analysis of results or to develop predictive procedures. Therefore, to develop holding capacity predictive procedures, a series of tests was conducted in coral at Barbers Point, Hawaii, using the CEL 10K propellant-embedded anchor; anchor, coral, embedment, and anchor pull parameters were measured. Also, a number of CEL 20K anchors that had been previously installed in coral at BARSTUR, Hawaii, were pull tested. In addition to these full-scale tests, two model-scale tests were conducted in a chalky limestone. Most of the pull tests ended in mechanical component failures rather than fluke extractions. A series of simple regression analyses of the various parameters measured indicated that the most important factors controlling holding capacity were fluke mass and velocity. Using only the tests where flukes were extracted, an equation for predicting holding capacity was developed as a function of kinetic energy.

Considerably fewer data are available on propellant-embedded anchors tested in rock seafloors than coral seafloors. Success has been mixed, with performance ranging from a failure of the fluke to embed to capacities exceeding the mechanical limits of the connective components and downhaul cables. Work on holding capacity in rock began with a series of model tests at NWC, China Lake, designed to study the ballistic and fluke characteristics that affect penetration. Seven different flukes were tested in a variety of rock types. A conical shaped fluke gave the most consistent performance in these tests. This fluke shape had less tendency to produce radial cracks in the rock which were observed to reduce holding capacity. Also, this shape has a uniformly increasing frontal area entering the rock surface which continually compresses the surrounding rock. As a result, this shape was observed to have larger surface areas covered with a comminuted rock coating than the other shapes. This coating is thought to contribute to frictional resistance to pullout.

Next, a series of model-scale tests were conducted at the White Sands Missile Range using the conical fluke shape in five rock types: basalt, limestone, granite, sandstone, and shale. Ballistic and fluke parameters were held constant. Penetration, rock fracturing, and holding capacity were observed to be dependent on rock type.

With the data from these tests as a base, trial predictive equations using selected anchor and rock parameters were tested against the data base. Some equations that resulted in a good fit to the data did not include fluke parameters that would allow for extrapolating the equation beyond the existing data base. A trial equation in which the holding capacities were normalized by the kinetic energy of the flukes offered both a best fit to the data and a means of extrapolating beyond the data base.

## CONCLUSIONS

1. The best equation for predicting the holding capacity of propellant-embedded anchors in coral is:

$$H = 0.024 \left[ \frac{1}{2} m v^2 \right]^{0.684}$$

where  $H$  = holding capacity, kN

$m$  = projectile mass, kg

$v$  = projectile velocity, m/sec

This equation is satisfactory for predicting the holding capacity of all the CEL propellant-embedded anchors. The single-sided lower 90% confidence limit is 45.3% of the predicted value. The use of this equation is limited to the range of parameters included in the data from which it was developed. It should not be applied to fluke shapes other than the CEL plate-like coral fluke. It should be applied with caution to installations in coral where properties are outside the limits of the data base. This equation could be improved by including the effect of coral strength.

## 2. An equation of the form

$$H = \frac{1}{2} m v^2 [f(\mu, \sigma, \rho, \dots)]$$

offers the best possibility of developing a general equation for predicting holding capacity in rock. An equation of this form will allow extrapolation to other anchor sizes. No trial equation gave suitable predictions for anchor sizes beyond the model scale used to acquire the data base. Data from full-scale 10K, 20K, 100K, and 300K propellant-embedded anchors will be necessary to develop a satisfactory equation.

3. Variations within each rock type tested had a large influence on performance. Of the 25 model tests performed in rock at White Sands Missile Range, only three flukes failed to embed, but three others provided minimal resistance to pullout. In each rock type where a poor result was observed, good results were also observed. In actual operational scenarios, provisions will be needed to accommodate an expected percentage of failures.

## RECOMMENDATIONS

1. The equation for predicting holding capacity could be improved by including the effect of coral strength. It is recommended that such an improvement be made by:

- a. Collecting more data as a part of every future installation
- b. Using downhaul cables and mechanical connections strong enough to achieve pullout during testing
- c. Thoroughly documenting test parameters

2. It is recommended that data be gathered from full-scale anchor tests in rock to provide an expanded data base for developing an equation to predict holding capacity in rock. These tests should:

- a. Include as many anchor sizes as possible
- b. Include tests where a given anchor is operated at different kinetic energies
- c. Be done in several rock types
- d. Use downhauls and mechanical connections strong enough to achieve pullout
- e. Thoroughly document test parameters
